## Acknowledgement

This Masters' thesis "Drilling Bit Perfomance Optimization Using DROPS Simulator" was prepared in the Spring of 2010 in collaboration with Conocophillips and Halliburton, TanagerNorway and Petroleum Engineering Department, University of Stavanger. Data were obtained from Conocophillips fields via Halliburton and simulated with DROPS Simulator provided by Impetro International, Oslo-Norway.

I would like to express my immeasurable thanks to Professor Bernt Aadøy ( Faculty Supervisor ), Jackob Steina and Knut Skinnaland (Impetro International), Mike Herbert (Conocophillips contact among others) and Tonje Helgaland (Sperry Drilling - Halliburton) for their encouragement, contributions and guidance.

My appreciation goes to God Almighty for his bestowed courage and strength for the completion of this project work. Thanks to my classmates and friends for their co-operations and understanding.

#### Abstract

Two drilled Wells: Well A and Well B were analysed under the following input data; drilling parameter, survey data, lithology data and bit information using DROPS simulator to showcase the bit performance optimization potentials. Apparent Rock Strength Logs (ARSL) were generated automatically by the simulator for the two drilled wells to give an idea of how hard is the formatiom and the rate of penetration possible for the bits. Interesting plots of the Apparent Rock Strength, Rate of Penetration, Weight on Bit, Revolution per minute, pump flow rate, Plastic Viscosity, mud Weight and Bit wear versus depth for the Well A and Well B were expressly presented in this project work. Appreciable cost per foot savings was made after the bit performance optimization simulation have been performed and a much more better savings could have been made if actual figures and parameters were used rather than assumed.

A better bit selection was made using ROP, drilling time, bit wear constant ( automatic evaluation by DROPS simulatior), bit cost and cost per foot for selection criteria.

Bit hydraulics analysis as relevant to cutting removal was adequately explained and evaluated for each bit used during the drilling in the bit performance optimization using the DROPS simulator.

## CHAPTER 1 INTRODUCTION

Drilling optimization Simulator (DROPS) is a program designed to facilitate the reduction of drilling costs for oil companies. This is done by implementing actual drilling data for relevant wells from the company and generating an Apparent Rock Strength Log (ARSL) sometimes referred to as Geological Drilling Log (GDL) for a field. Once a proper ARSL has been generated, the user can easily simulate the forthcoming wells in that particular field.

The Apparent Rock Strength Log (ARSL) and its creation forms the basis for all simulations performed in DROPS Drilling Simulator (later referred to as DDS). The ARSL is a representation of the rock strength in a particular well or section, derived from the actual historical drilling data. When an ARSL has been generated and professionally verified for its accuracy, the planning of the drilling of any well is facilitated through its availability. The user can use DDS to simulate and test different makes as well as geometrical and hydraulic properties of drill-bits and thereby the detailed planning of the drilling of a well can be based on the simulated optimal cost. The ARSL is created by using reported Rate of Penetration (ROP) based on data from the field. The required three data registers for generating an ARSL are <BITFILE>.bit, <DRILLFILE>.drill, and <LITHOLOGY $>$.lith. The survey file $<$ SURVEY $>$.path is optional in terms of the actual ARSL creation.
<BITFILE>.bit shall contain the detailed information about the drillbits that were actually used in a particular section with in-depth description of each bit as specified. The bit file is recognized by the *.bit file extension.
<DRILLFILE>.drill shall contain all relevant operating parameters and other data for the particular section that will be used for the generation of an ARSL.

The operation data file is recognized by the *.drill file-extension.
<LITHOLOGY>.lith shall contain all relevant information about the types of formations in the selected section, this is done by listing the percentage of occurrence of the different rock types. The lithology file is recognized by the *.lith file-extension.
<SURVEY>.path shall contain all relevant information about the directions and changes in direction that occurred during the drilling of the section. The survey file is recognized by the *.path extension.

Once the program has generated the ARSL or GDL, it verifies that it is accurate according to the relevant theoretical ROP models by performing a DrillBehind(Appendix). The DrillBehind conducts a reverse ARSL calculation, where the calculated apparent rock strength is used to calculate the theoretical ROP, this is then compared to the field reported ROP. Both the ARSL creation and the Drillbehind are automatically performed by the program and do not require the user to do anything but to prepare the input files needed. ${ }^{2}$

The Simulator optimizes two wells from the Ekofisk/Eldfisk field: Well A and Well B.

## CHAPTER 2

## LITERATURE REVIEW

The drilling bit is arguably the most amazing tool on the rig. Its operating environment, thousands of meters below the surface is the most hostile. Its duty, the destruction of rock millions of years old is the most demanding. We routinely pump thousands of gallons of mud through it; apply thousands of weight to it while simultaneously spinning it at different RPM. If it does not perform properly, a multi-million dollars drilling rig is wasted tripping pipe hence optimizing drill bit performance and drilling optimization at large is recommended.

With so much riding on the drilling bit, it is imperative that we select the best bit available which will produce the lowest cost per foot. Bit selection should involve more than just a check of what was run on the last well, or simply running what you happen to have on location. Selecting a bit should be a reasoned, conscious effort because it is a choice the entire operation is going to have to live with for the next several hours while the bit is on bottom.

Bit performance optimization addresses two issues:

First, a bit must be selected for the upcoming bit run which will stay in the hole a long time and give overall penetration rates.

Second, the bit must be operated properly while on bottom and while running-in so that we do not needlessly reduce its potential.

The basis for selection of a particular drilling bit is cost per foot. We want to select the bit which will provide the lowest cost per foot over the upcoming interval. This decision will involve an investigation into a variety of wellbore factors including formation hardness and hole angle. In addition, there are design aspects to all drilling bits, such as offset and journal angle, which make them superior performers in specific environments. Bit design is at the heart of proper bit selection.

### 2.1 ROLLER CUTTER ROCK BITS - DESIGN FEATURES

This section describes the components of a roller cutter rock bit and the variations which are possible to tailor a bit to drill a specific formation.

## Bearings

There are three basic types of bearings utilized in roller cutter rock bits;
-The non-sealed roller bearings.
-The sealed and lubricated roller bearings.
-The sealed and lubricated journal bearings.

The choice bearing depends on the wellbore environment and cost per foot economics.

Non-Sealed Roller Bearings (NSRB) are the least technically advanced of the bearing types and are generally the least expensive. They incorporated an anti-friction roller bearing between the inside of the cone and the leg. The roller bearing supports the radial load which is placed on the cone when weight is applied to the bit. There is also a friction bearing in the nose of the cone which takes some of the radial loading. In addition to roller bearings, these bits also include a race of ball bearings which support the longitudinal loading applied to the cone. These ball bearings also keep the cone from falling off of the leg or from being driven into the shirt tail of the bit.

Figure 2.1 Typical Roller Bearing Construction.

As the name implies, the bearing assembly is neither sealed or nor grease lubricated, and drilling fluid is free to make its way into the workings of the bearing. As a result, solid particles in the mud abrade the metal of the rollers and races and the cones become "loose". A loose bearing cannot evenly distribute the load, and continued rotation causes severe metal loss at the contact points. The ball bearings begin to take radial loading until, finally the bearing is shot and the cones are at risk of being lost in the hole.

Non-Sealed Roller Bearing are usually recommended on large diameter milled steel tooth bits. These bearings can usually last as long as the cutting structure because the bearing surface is relatively large and the drilling weight are small. These bearings may also be found on bits used to drill out short runs of cement within casing or when high RPMs are required for short durations.

Sealed and Lubricated Roller Bearings (SLRB) also uses roller and ball bearing elements to support the drilling load that is applied to the bit. However, SLRB's include a sealed between the back face of the Cone and the leg which effectively eliminates drilling mud invasion into the workings of the bearing. Because the bearing is sealed, it is possible to keep it well greased. SLRBs contain grease reservoirs which have connecting passages to the bearing cavities. The reservoir is covered by a flexible rubber diaphragm which allows wellbore hydrostatic pressure to equalize as the bit is being run or pulled from the hole.

As a result of these design enhancements, SLRBs can be expected to last longer than NSRBs but there widespread application still remains in conjunction with milled tooth cutters. One objective in bit selection is to choose a bit which will become dull at about the same time that the bearing wear out. Tungsten carbide insert cutters will almost always outlast a sealed roller bearing.

Since sealed bearing life is more a function of bit weight than rotary speed, the higher weights required to drill smaller holes at deeper depths can be especially destructive to the rollers. On the other, in a soft abrasive formation, it is possible that the bearings outlive the milled teeth. Most bit manufacturers recommend a maximum bit weight of 5000 lbs per inch of bit diameter for sealed roller bearing bits. If it takes most of this weight to make the bit drill acceptably, serious consideration should be given to running a journal bearing bit on the next trip.

In a Sealed and Lubricated Journal Bearings (SLJB), the radial load is distributed over a much larger area than that in a roller bearing. As a result, more loads can be supported without metal deformation or fatigue. Instead of a series of rollers to bear the radial load, the journal bearing makes use of two circular bearing surfaces which mate within very close tolerances of each other. A thin layer of grease must separate the two surfaces to prevent seizing and galling, so a grease reservoir and injection mechanism is employed. Dirt and contamination is especially harmful to journal bearings, so a highly effective "O" ring seal is used to keep grease in and trash out.

There are two methods of cone retention which are used on journal bearing bits. The conventional system uses ball bearing to support the longitudinal loads, just as in roller bearing bits. However, the Hughes Tools Co. system uses a lock ring instead of ball bearing to secure the cones to the leg and to absorb the thrust loads. The lock
ring occupies much less space than the ball bearings, so the journal surfaces can be significantly larger (and support more bit weight without falling).

Journal bearing are also sometimes called friction bearings and they can generate a lot of internal heat as they rotate. The tight clearances found in the bearings leave little room for the heat of rotation to dissipate. Hence it is important not to spin a journal bearing bit too fast.

Figure 2.2 Typical Sealed Journal Bearing construction.

## Cutting Elements

The cutting elements found on roller cutter rock bits are either made of milled steel (teeth) or tungsten carbide inserts. The length, shape and spacing of the cutters generally adhere to the following design philosophies:

Soft Formations composed of materials having low compressive strengths (less than 5000 psi ). Typical soft formation materials are clay, shale, loosely cemented sand, chalk and soft limestone. In soft formations, the biggest concerns with milled teeth are bit balling and abrasive wear. A bit is said to be "balled" when sticky formation is paced so tightly in between the teeth that it holds the teeth away from the face of the formation.

The problem is solved by placing fewer teeth on each cone. This leaves more room between the teeth so that the sticking formation is not nearly as well supported and is more easily dislodged. Tooth wear is a problem because soft formation bits are designed to drill with a gouging and scraping action which is inherently abrasive.

Bit designers minimize this problem by adding tungsten carbide hard-facing to the teeth. The teeth are as long as possible into the formation to generate the largest cuttings.

When tungsten carbide insert teeth are used, abrasion is not a concern due to the exceptional wear resistance of the material. Long inserts are used for maximum bite, and are usually chisel or conical in shape. However, bit balling remains a problem, so the inserts are spaced widely apart with a good degree of tooth interfit.

Medium Hard formations are composed of material having moderate compressive strengths between 5000 and 10000 psi. Typical medium hard formations include limestone and sandstone. In medium hard formations, the bit relies on a combination of chipping and twisting action to make hole. Milled tooth breakage becomes a problem because higher drilling weights are required; so the teeth are shorter and less pointed. Hard-facing is still applied to the inner rows of teeth to make the bit more versatile under a variety of conditions.

The teeth on insert bits are more closely spaced to reduce the incident load on each tooth while maintaining high protrusion. The inserts are more conically shaped and
blunter. The inserts' resistance to abrasion allows the bit to incorporate a fair amount of offset to still produce a gouging action.

Hard Formations are composed of material having high compressive strengths (greater than $10000 \mathrm{psi})$. Typical hard formations include dolomite, hard limestone, granite and chert. In hard formation, the rock destruction mechanism is primarily by crushing. The milled teeth impact directly on the formation face and pulverize it. With high drilling weights, the bending forces on a tooth can be severe so the teeth are short, stubby and numerous to minimize breakage. Because there is very little tooth scraping action, hard-facing is usually applied only on the gauge row of teeth.

Insert are set deeply into the cone with little protrusion to reduce their tendency to pop-out. The inserts have a spherical or elliptical shape.

## Pitch Breaks

Pitch is the distance between adjacent teeth on a bit cone. If the pitch is the same for all teeth on a given row, then there is a tendency for the bit to track the same path against the formation on each rotation. When this occurs, the teeth impact the formation in the same location on each rotation, resulting in the generation or 'rock teeth' into which the bit teeth mesh. When this occurs, the bit will simply track round and round into the rock teeth without making any hole. To prevent this from happening, the pitch between the teeth is varied. This results in a cutting pattern variation on each revolution which destroys the rock teeth as soon as they are generated.

## Cone Offset

When the axis of rotation for the three cones of a bit does not converge at a common point at the center of bit rotation, the cones are said to be offset. The degree of offset is measured perpendicularly from a point on the cone axis to the center of bit rotation. The effect of offset is to cause the cone to want to rotate through a different arc than the one to which the bit body has it constrained. This causes the cone to slip which scrapes and gouges the formation rock in front of the bit. Soft formations are especially responsive to this type of cutting action and drill well with a high amount of cone offset. In harder formations, where the rock must be physically broken or fractured, the scraping gouging action produced by cone offset contributes little to rock removal. In addition, scraping and gouging against a hard formation is very abrasive to the cutting structure,
and can wear the teeth down quickly. As a result, hard formation bits are designed with little or no cone offset.

Figure 2.3 Cone Offset

## Journal Angle and Cone Angle

The journal angle is the angle measured between the cone axis of rotation and a horizontal plane; it is the angle on which the cones are mounted to the bit. If the axis of rotation of the cone is parallel to the bottom of the bit, then the cone has zero journal angles. Most cones are mounted with a journal angle between 33 and 37 degrees which increases to suit harder formations.

Figure 2.4: Cone Journal Angle

The cone angle is the angle formed by the outside profile of the cone. Most cones have either two or three cone angles, depending on the number of rows of teeth.

Figure 2.5: One cone angle of a bit.

The cone angle and journal angle interact to help generate the specific cutting action of the bit. As the cone angle approaches a value which is twice that of the journal angle, the cone profile becomes flush with the bottom of the hole. This creates a true rolling motion which is suitable for hard formation bits. If the cone angle is less than twice the journal angle, the outer rows of teeth will want to rotate faster than the inner rows of teeth which cause a gouging/scraping cutting action suitable for soft formation bits.

Small journal angles increase the radial load on the bearing, but also provide the most room for bearing design. As a result, the bearing and cone diameter can be larger (which is preferable for soft formation bits). One drawback to a small journal angle is the need to trim the outer base of the cone so it does not extend beyond the shirttail and create over-gauge conditions. This increases the gauge reaming area of the cone which can cause problems in a abrasive environment. Larger journal angles increase the thrust load on the bearing, and by necessity require that the cone angle be smaller.

## Interfit

The degree to which the teeth from one mesh within the spaces between the rows of teeth on another cone is called interfit. The teeth do not actually mesh as in a gear, but rather a relief ring is cut into the surface of a one cone to provide space for the tooth rotation of an adjoining cone. Interfitting the cones gives the bit designer more room to build better components with. The result may be longer teeth for soft formation bits or bigger bearings for hard formation bits. Interfitting also helps to prevent bit balling, as the teeth serve as a mechanical way to dislodge sticky cuttings.

When interfitting is used to produce longer teeth, the effective cone angle is increased. This will normally increase the degree of gouging/scraping action unless the journal angle is also increased, which may be impractical. For this reason, high degrees of tooth interfit are usually associated only with the soft formation bits.

## Nozzles

Nozzles and nozzle placement are an important aspect of bit design. The purpose of the nozzle is to normally increase the velocity of the mud as it exits the drillstring. High velocity fluid flow is advantageous at the bit. Nozzles are made of tungsten carbide for washout resistance.
Effective nozzle placement is critical both for cutter cleaning and formation erosion. However, the two cannot be fully accommodated simultaneously. To optimize cutter cleaning, the high velocity fluid stream leaving the nozzle is directed at the cones in a glancing angle. Direct impact on the cutters would cause maximum cleaning but unacceptable fluid washout of the cone itself.

The high velocity stream fluid loses its energy as it travels through the mud once it exits the nozzle. Therefore, for maximum hydraulic formation erosion, the fluid should exit the nozzle just above the formation face. Unfortunately, that area is occupied by bit manufacturers have gone to two cone bits which have the necessary space needed to extend the nozzle below their normal location within the bit body. These so-called "extended nozzle bits" have found to be very effective in certain formations, while not so effective in others. Tri-cone extended nozzle bits are also available. The main formation characteristic which seems to be conducive to high penetration rates when these bits are used is erodibility.

A bit cleaning problem arises with extended nozzle bits because the cutters are not impacted and cleaned by the energy fluid flow. As a solution, center jets are run to direct flow over the cones and clean the teeth before formation contact.

### 2.2 ROLLER CUTTER ROCK BITS - BIT SELECTION AND APPLICATION

In 1987 the IADC revised its system for classifying roller cone rock bits. The new IADC codes based on a 4-character designation which describes the bit's cutting structure, formation compatibility and any special features. The old code used a 3-chracter designation which had become inadequate since its adoption in 1972.

The new code is designed to include special designators for recent technical advances and also allow sufficient room for the code to expand as bit designs continue to evolve.

Figure 2.6: IADC bit code.

The first character of the code is a numeral which indicates the type of cutting structure found on the bit.

The second character of the code is a numeral which indicates the relative hardness of the formation for which the bit was designed to drill.

The third character of the code is a numeral which indicates the standard bearing features of the bit.

The fourth character of the code is a letter which indicates any special features of the bit.

### 2.2.1 Tooth Series (Numerals 1-8):

Numerals 1-3 indicate the bit has milled steel teeth. Smaller numbers indicate fewer and longer teeth for soft formations while higher numbers indicate more but shorter teeth for hard and abrasive formations.

Numerals 4-8 indicate the bit has tungsten carbide insert teeth. Smaller numbers indicate fewer and longer teeth for soft formations while higher numbers indicate more but shorter teeth for hard and abrasive formations.

### 2.2.2 Formation Type (Numerals 1-4):

Within each series the formation is subdivided into four types depending on relative formation hardness. Smaller numbers indicates soft formations relative to the tooth series while higher numbers indicates hard formations relative to the tooth series.

### 2.2.3 Standard Features (Numerals1-7):

The numerals indicate the type of bit bearing and the presence of gauge protection.
They are:
1 - Standard Roller Bearing
2 - Air Cooled Roller Bearing
3 - Roller Bearing with Gauge Protection
4 - Sealed Roller Bearing
5 - Sealed Roller Bearing with Gauge Protection
6 - Sealed Friction Bearing
7 - Sealed Friction Bearing with Gauge Protection

### 2.2.4 Special Features (Letters A-Z)

These letters indicates any special features which the bit may have. They are:
A - Air Application
C - Center Jet
D - Deviation Control

E - Extended Nozzles
G - Extra Gauge Protection
J - Jet Deflection
R - Reinforced welds
S - Standard Steel Tooth (no special features)
X - Chisel Shaped Inserts
Y - Conical Shaped Inserts
Z - Other Insert Shape

### 2.3 ROLLER CUTTER ROCK BITS - OPERATING PROCEDURES

The moment a bit passes through the rotary, it begins to wear out. The trip to the bottom of the hole can be arduous one. Wellbore obstructions such as blowout preventers and under-gauge hole can act to wear a bit out before it ever makes us a single foot of hole.

Proper operation of a bit is at least as important to a good bit run as the bit selection itself. This section will discuss those actions which we should practice to avoid needlessly detracting from a bit's hole-making potential.

## Surface Bit Handling

When a new bit arrives on location, it may or may not have nozzles in it. Bits should be ordered without jet nozzles installed. If a bit shows up with nozzles already in it, it should be removed. This will give an opportunity to dress and inspect the bit when it is next in the hole. Do not doghouse your hydraulic calculations and have the bit peddler similarly dress all bits with three twelve. Make sure the bit peddler has left a variety of nozzles to cover all expected operating conditions.

New bits should be stored in their boxes in a dry place. It is best to place them on pallets to keep them out of the mud. The bit serial number should be recorded in the rig's bit inventory with the date of arrival. Re-run bits should be hosed-off, re-greased if possible and stored with a liberal coating of pipe on the threads.

## Picking-Up the Bit

When the decision has been made to run a particular bit in the hole, the drill bit should be inspected thoroughly which should include:

- A check to see that the box has not been mislabeled and that the type of bit to be run is actually contained within.
- A check to see that the bit has the desired features such as gauge protection and proper insert shape.
- Inspect the bit for any broken teeth, missing inserts, or protruding bearing seals. Make sure the grease reservoir equalization ports are not clogged.
- Always check and record the bit diameter with a gauge ring regardless of whether it is new or re-run.
- Always use a lifting eye when bringing the bit up to the rig floor. Do not use slings which can slip off and injure someone or damage the bit.
- The drilling representative should witness to nozzles installation. Proper nozzle installation is a simple but critical operation which the drill rep should be well practiced in.
- Always use new nozzles and accessory equipment such as o-rings and retaining rings.
- Never force a nozzle into the bit body or tap on it with a hammer (nozzles are made of tungsten carbide and are very brittle).
- Confirm the size of the nozzle opening with a nozzle gauge.

The bit should be made up with a properly sized bit breaker in good mechanical condition.
-Clean the threads of all foreign substances before applying dope.

- Use the recommended make-up torque for the bit thread form but remember, new tool joints need to be made-up slowly to prevent galling.

## Tripping in the Hole

The bit should be always being passed as slow as necessary to get through known ledges or restrictions in the wellbore. There are both cased hole and open hole restrictions with which we must be concerned. Blowout preventers, casing heads, whipstocks, liner tops, casing patches and casing shoes, all present steel obstruction which can prevent a bit form passing. Hitting these obstructions too fast can break teeth and damage bit bearings. Drillstrings have also been known to jump the elevator when bits have hung-up while running in the hole. Even if a potential
obstruction such as a casing shoe has never been a problem, it should be approached cautiously each time while running-in.

Bits have the ability to worm their way through an obstruction that other full-bore tools cannot. A little rotation is necessary at times to get through a liner top but indiscriminate reaming inside casing with a bit is never recommended; a swage or dressing mill is more appropriate for these purposes.

Once the bit is in open hole, potential restrictions may not be so predictable. Running-in speed will generally be reduced in open hole with a close eye kept on the weight indicator. Special care should be taken when approaching those areas which were tight on the way out of the hole. Reaming may be necessary to get back to bottom but keep in mind that excessive reaming can damage a bit. Low bit weighs, fairly high rotary speeds and lots of pump should be used while reaming. Remember that the weight you are applying is being supported only by the outer row of gauge teeth on the bit and that while the total weight being applied at the surface may be small, the psi loading on the gauge teeth will be very high. Reaming also produces a very unbalanced loading condition for the bearing and damage may result over prolonged periods.

Do not force the bit into a situation from which you cannot retrieve it. Do not ream an entire Kelly down without checking to see if you can pick it up. Unless the rig is equipped with a top drive, it probably would not be able to up-ream. Being stuck with a buried Kelly is no fun!

## While on Bottom

As a new bit approach the bottom, it is good practice to pick up the Kelly and wash the last two joints to bottom. Avoid running into fill as this may plug your nozzles or ball the cutting structure. Bring the pumps online slowly to prevent pressure surges which can blow the nozzles out of the bit. If junk is suspected on bottom, give your pumps a chance to circulate it up into the junk basket before making hole.

When drilling is started, low weight and rotary speed is used to break-in the new bit. The few minutes gained by quickly "running heavy" on a bit can easily be negated by early bearing damage and a resultant short bit run. Wait until the bit has established its new bottom-Hole pattern and has drilled a couple of feet before really stacking-it-out for the first drill-off test.

20mater

Do not exceed the manufacturer's published maximum bit weight and rotary speed without first consulting the Drilling superintendent.

Drill shale and other plastic formations with high RPM and low weight to reduce the chances of bit balling.

Drill lime, dolomite and brittle formations with high weight and low RPM to induce fractures. Drill abrasive formations with the lowest RPM to reduce gauge wear.

## Pulling Out of the Hole

When a bit is dull and being pulled out of the hole, it still has the potential to lower the cost per foot of the next bit in the hole. Tight spots encountered while pulling out of the hole should be reamed with the dull bit being pulled rather than the new bit on its way in the hole. In this manner, the life of the new bit may be extended because it will not have to ream as much.

### 2.4 ROLLER CUTTER ROCK BITS - DULL BIT GRADING

In 1987 the IADC revised its system for grading used roller cutter rock bits. The new IADC codes are based on an 8-character designation which describes the bit's remaining cutting structure, bearing condition and gauge condition. The old code used a 3-character "T,B,G" designation which had slowly become inadequate since its adoption in 1961.

The new code is designed to include special designators for specific wear patterns observed on both fixed cutter and roller cutter rock bits and to include the reason the bit is pulled. An example using the new IADC grading system is explained in the figure below.

Figure 2.7: Revised IADC Code

Inner Rows (Numerals 0-8): indicates the reduction in cutting structure on the inner rows of teeth due to loss, wear, or breakage. Smaller numbers indicates less reduction.

Figure 2.8: Dull Cutting Structure Grading

Outer Rows (Numerals): indicates the reduction in cutting structure on the outer rows of teeth due to loss, wear or breakage. Smaller numbers indicates less reduction.

Dulling Characteristic (2-letter Codes): indicates any extraordinary wear patterns observed on the cutting structure of the bit. These are:

> BC - Broken Cone
> BT - Broken Teeth

BU - Balled Up
CC - Cracked Cone
CD - Cone Dragged
CI - Cone Interference
CR - Cored
CT - Chipped Teeth
ER - Erosion
FC - Flat Crested Wear
HC - Heat Checking
JD - Junk Damage
NO - No Extraordinary Wear Detected
LC - Lost Cone
LN - Lost Nozzle
LT - Lost Teeth
OC - Off Center Wear
PB - Pinched Bit
PN - Plugged Nozzle
RG - Rounded Gauge
ST - Shirttail Damage
SS - Self-Sharpening
TR - Tracking
WO - Washed-Out
WT - Worn Teeth

Location (Alphanumeric): Indicates the location of the extraordinary wear described in the Dulling Characteristics. These locations are:

N - Nose Rows of Teeth
M - Middle Rows of Teeth
H - Heel Rows of Teeth
A - All Rows of Teeth
1 - Number One Cone
2 - Number Two Cone
3 - Number Three Cone

Bearing (Alphanumeric): Indicates the reduction in non-sealed bearing life using a linear scale from 0-8. Smaller numbers signify less wear. Use an "F" (failed) or an "E" (effective) to signify the seal condition when sealed roller or journal bearings are used.

Gauge ( $\mathbf{1 / 1 6 " ) : ~ I n d i c a t e s ~ t h e ~ d e g r e e ~ o f ~ g a u g e ~ w e a r ~ o n ~ t h e ~ b i t ~ r e p o r t e d ~ i n ~ s i x t e e n t h s ~ o f ~ a n ~ i n c h . ~}$ Use an "I" if the bit is in gauge.

Other Dulling Conditions (2-letter Code): Indicates any additional extraordinary dulling condition not reported elsewhere in the report.

Reason Pulled (2- or 3-letter Codes): Indicates the reason for the bit out of the hole. These are:

$$
\begin{aligned}
& \text { BHA - Change BHA } \\
& \text { DMF - Mud Motor Failure } \\
& \text { DSF - Drillstring Failure } \\
& \text { DST - Drill String Test } \\
& \text { DTF - MWD Failure } \\
& \text { LOG - Run Logs } \\
& \text { CM - Condition Mud } \\
& \text { CP - Core Point } \\
& \text { DP - Drill Plug } \\
& \text { FM - Formation Change } \\
& \text { HP - Hole Problems } \\
& \text { HR - Hours on Bit } \\
& \text { PP - Pump Pressure } \\
& \text { PR - Penetration Rate } \\
& \text { RIG - Rig Repairs } \\
& \text { TD - Total Casing Depth } \\
& \text { TO - Torque } \\
& \text { TW - Twist Off } \\
& \text { WC - Weather }
\end{aligned}
$$

### 2.5 PDC BITS - DESIGN FEATURES

The PDC bit is a one-piece cutting tool using numerous polycrystalline diamonds compact to cut the rock. The polycrystalline diamonds cutters consist of a thin layer of synthetic diamonds adhere to a tungsten carbide disc.

Figure 2.9: Typical PDC construction

These compacts are produced as an integral blank by a high pressure, high temperature process. The diamond layers of many tiny diamond crystals which are bonded together with their cleavage planes randomly oriented to each other so that shock-induced breakage in an individual diamond crystal does not propagate though the entire cutter. This result is a wafer thin diamond layer with the hardness and abrasion resistance of a diamond and the impact resistance of tungsten carbide. These bits are a high technology revival of the first type of rotary drilling bit the drag bit.

PDC bits drill by shearing the rock rather than crushing it as rock bits do or grinding it as natural diamond bit does. Rock fails with significantly less energy in shear than in compression, thus a more efficient drilling action can be obtained with less WOB.

In the right formation, PDC bits can drill long and hard. They routinely double the time in the hole and triple the footage of conventional roller cone bits but running PDC bit in the wrong formation will quickly destroy it.

Figure 2.10: PDC Bit Cutting Action (shearing)

PDC bits are expensive and unforgiving. They can be destroyed by hard formations or rendered impotent by gumbo-type formations. Their application should never be indiscriminate. Instead, PDC bits should be put in the hole only after a detailed analysis of formation lithology has been performed and a compatible formation with sufficient thickness has been predicted to make a PDC bit run economical.

The technology of PDC bits is evolving rapidly. As a result, there are many bit designs available from a variety of vendors all trying to approve their product's superiority. A detailed field analysis of these designs has yet to be completed, leaving it difficult to determine the best designs. In many instances, it will be necessary with only a small amount of data to help.

Figure 2.11: Typical PDC Bit Nomenclature

## Bit Body Material

The material which is used to make the body of a PDC bit takes a real beating while drilling. Because these bits stay in the hole a long time, the possibility for fluid erosion and mechanical abrasion of the bit body is a real possibility. Most PDC bits experience some fluid erosion while drilling, but this only becomes a problem if the bit body material washed out to the point where a nozzle or a PDC cutter is lost in the hole. When PDC bits are in the hole, junk begets more junk and bit is quickly destroyed.

Basically, there are two types of body materials for PDC bits:
Steel and Tungsten Carbide matrix

Steel Body: The most common and inexpensive bit body material is heat treated steel. These steel body bits are usually used in conjunction with PDC "studs" which are diamond compacts on tungsten carbide posts. These stud cutters are typically secured to the bit body by interference fit or shrink fit into a hole located in the bit body.

Figure 2.12: PDC Stud Cutter

Steel body bits usually incorporate three or more carbide nozzles (often interchangeable), and carbide buttons on the gauge length to resist wear. Steel body bits have limitations due to fluid erosion of the bit face by drilling mud and the wear of the gauge section. Some steel body bits are offered with wear resistant coatings applied to the bit face to limit mud erosion.

Steel body PDC bits will generally perform well in most soft to medium formations. Body erosion will usually not be the limiting factor which brings the bit runs to an end unless super-high flow rates are in use. In those instances where loss of body material is a problem through abrasive formations, a matrix body should be used.

Matrix Body: A second type of bit body which is much more abrasion and erosion resistant than the steel body is the matrix body. The matrix bit body is composed of a combination of copper and tungsten carbide to provide durable wear resistance. Greater bit design freedom is generally available with tungsten carbide matrix body bits because they are "cast" in a mold as are natural diamond bits. Thus, matrix body bits typically have more complex profiles and incorporate cast nozzles and waterways. In addition to the advantages of advanced bit face configuration and erosion resistance with matrix body bits, PDC matrix bits often use natural diamonds on the gauge hole. Matrix body bits generally have long cylinder shaped cutters secured directly to the bit by brazing.

Matrix body bits will usually not drill any faster than their steel body brothers but they can stay in the hole longer if formation abrasion has been a problem. Matrix body bits are more expensive than steel body bits.

## Bit Profile

Bit profile can significantly affect bit performance. The bit profile will have a direct influence on bit cleaning, bit stability and hole deviation control. Several bit profiles are offered with specific design motivations behind each.

Parabolic

Shorl Concave

Step

Figure 2.13: PDC Bit Profile

Parabolic: The parabolic or "sharp" nose profile is designed for soft and sticky formations. This bit profile will attack and drill the formation aggressively while the apex and reaming flank stabilize the bit. Conversely, the long taper profile may be more vulnerable to damage when a hard stringer is encountered as only the cutters on the nose will support the impact loading. It is possible to build and drop angle to a limited degree with these bits but they will often exhibit a tendency to walk to the left through harder formations.

Short Concave: The short concave profile shown above is designed to drill medium strength formations but also tends to help maintain a straight hole. Building or dropping angle with these bits is difficult due to the few numbers of cutters on the flanks. This profile relies heavily upon a long gauge section for directional stability. These bits should always be run with stabilizer on top of them to assure that the bit face is seated evenly on the bottom of the hole so that the drilling fluid is evenly distributed. The short concave cone profile appears to be the easiest to clean due to the concentration of hydraulics on the reduced surface area of the bit face.

Step Profile: The step profile shown above places the cutters at maximum exposure from the body of the bit. On these bits, an individual cutter will make contact with the formation on both the bottom and sides of the hole. The resulting dual cutting action creates both horizontal and vertical shearing of the rock which may increase
bit stability, deviation control and penetration rate. The dual contact produces high stresses on each cutter so these bits operate with less total weight on bit. This makes step profile bits good candidates for mud and turbine runs where high speeds but low weights need to be run.

## Cutter Placement

The number and placement of cutters on a bit depend upon the formation being drilled, the bit design and style, the expected operating limits and the hydraulics design. Generally, the greater the cutters concentration, the lower the wear rate and lower the rate of penetration. High numbers of cutters are usually placed on the harder formation bits which reduce the load per cutter and the occurrence of PDC breakage. Fewer numbers of cutters are placed on soft formation PDC bits to reduce the chances of bit balling.

PDC cutters are available in a wide variety of patterns, too numerous to mention here. Until a clearly superior pattern steps out from the rest of the crowd, the determination of the best designs will have to be determined by trial and error.

## Cutter Exposure

Cutter exposure is the distance between the cutting edge and the bit face. See figure 2.14 for diagrammatic details. Steel body bits which use stud cutters typically have full exposure which proves very aggressive in soft formations for maximum hole making potential. In harder formations, less than full exposure may be preferred for added cutter durability. Partially exposed cutters are harder to clean and are most often found on matrix body bits which are backed-up with matrix material to give the cutters added strength.

## (Partially Exposed)

## Figure 2.14: PDC Exposure

## Cutter Clearance

Another PDC bit enlargement is a cavity which is cut into the face of the bit to provide clearance for cuttings removal. Without the clearance area, cuttings may "jam up" in front of the cutter and inhibit further cuttings generation. The clearance area provides a cavity for the newly created cuttings to peel into before they are circulated away to the outside of the bit.

Figure 2.15: Clearance Area

## Cutter Orientation

The orientation and direction of the cutters on a PDC bit play a major role in determining the bit's cutting action. Bit designers can alter the angle of attack of individual cutters against the formation to vary the bit's rock shearing mechanism. The side rake angle and back rake angle are two PDC parameters which will determine a PDC bit's effectiveness in drilling through a specific formation.

The action of the PDC bit drilling through rock is similar to that of a snow plow. Just as the angle and depth of the snow plow is adjusted to suit specific snow conditions, the back and side rake angles of a PDC cutter are set to produce optimum penetration rates. The back and side rake angles describe how the face of a PDC cutter is oriented with respect to the body of the bit.

## Back Rake Angle

When a PDC cutter has no back rake, the face of the cutter is orientated straight up and down in a plane which is parallel to the longitudinal axis if the bit. With 0 degrees back rake on a cutter, the angle formed between the formation and the face of the cutter is 90 degrees. A pictorial representation of back rake is provided in the figure below.

Figure 2.16: Back Rake Angle

When back rake is added, the bottom edge of the figure 2.16 - Back Rake Angle cutter is tilted away from the direction of rotation, so that the angle of incidence with the formation is less than 90 degrees. The addition of back rake increases the life of a cutter because the cutting edge is less susceptible to micro-chippage caused by shock induced loads which can occur when hard stringers are encountered. Also, cutters which are set with a back rake will usually run smoother with less torque. By the same token, back rake makes a cutter less aggressive and creates more of a tendency for the cutter to slide over the formation face rather than shear it. For this reason, penetration rates will usually be lower.

Back rake angles usually vary between 0and 25 degrees, depending on the overall formation hardness and the likelihood of encountering hard streaks. The addition of back rake will not make a PDC bit drill any through hard sections but it will allow the bit to drill through it with sustained damage.

## Side Rake Angle

Side rake describes the radial orientation of the face of a PDC cutter to the bit body. With no side rake, the face of the cutter is situated parallel to a radial line drawn from the center of the bit. When back rake is added, the outer edge of the cutter is tilted away from the direction of rotation so that the angle exists between the face of
the cutter and the radial line. This angle is called the side rake angle. Side rake on a PDC cutter performs the same function as angling the direction of a snow plow blade.

Angling the snow plow blade causes the snow to be directed to one side of the plow. Adding side rake to a PDC cutter causes a mechanical displacement of the cuttings to the outside of the bit where they are more easily removed and circulated up the junk slots in the bit. Side rake helps to the cuttings from jamming-up underneath a PDC bit and therefore reduces the chances of bit balling. Figure 2.19 shows how a PDC cutter is placed with a positive side rake angle.

Figure 2.19: Side Rake Angle

## Bit Hydraulics

Bit hydraulics is more important to PDC bit performance than to other bit types. PDC bits drill fast and generate large cuttings which must be removed from the face of the bit and up the annulus. Depending on bit profile, the cuttings path from cutter to annulus may be quite tortuous and bit balling is a possibility if they get hung-up along the way. The nozzles on PDC bits are located very close to the bottom of the hole and this aid greatly in cutting removal.

PDC bits are designed with 3-7 nozzles where mud enters the face of the bit from the inside of the drill pipe. Junk slots are cut into the gauge lengths of the bit to serve as fluid exit points from the
face of the bit. Mud and cuttings are transported to the junk slots through watercourses cut into the face of the bit or by natural flow paths defined by cutter placement. Effective bit design involves placing the nozzles, junk slots and watercourses in a way which produces the optimum flow pattern for cutter cleaning and cooling.

The penetration rate of PDC bits through soft formations is usually limited only by the hydraulic cleaning effectiveness. As pump volume or hydraulic energy is decreased, penetration rate is reduced as cutting removal slows. This results in a regrinding of the cuttings or the possible clogging or balling of the bit.

It is usually assumed that hydraulic horsepower rather than impact force is the necessary ingredient to have at the bit to create good cleansing turbulence. Generally, hydraulic horsepower at the bit should be in the range from 2.5 to $4.5 \mathrm{HP} / \mathrm{in}^{2}$ for steel body bits and up to $7.5 \mathrm{HP} / \mathrm{in}^{2}$ for matrix bits in sticky formations.

### 2.6 PDC - BIT SELECTION AND APPLICATION

## Compatible Formations

The PDC bit is best suited to drill soft to medium sedimentary formations. Since it drills with a shearing action, it is most effective when drilling formations that fail easily in shear. Some of the most compatible formations for drilling with PDC bits are clays and shale. Good PDC bit runs have also been obtained through evaporate formations such as gypsum, anhydrite and rock salt. While sandstone does not fail in shear, good runs have been reported through soft sandstones that are not well cemented or too abrasive.

The PDC bit is not a good choice to use in hard formations. The brittle PDC cutters can be easily destroyed by hard formations such as chert, granite, calcite and hard dolomite. In addition, wellcemented sedimentary sandstones should not be drilled with PDC bits because of their abrasive nature.

It should also not be used in sticky formation such as "gumbo shale" because the bit is likely to be ball-up. Several manufacturers are working on new versions of their PDC bits with improved hydraulics to serve this application.

## Tri-Cone Applications

Formations which may drill well with PDC bits can sometimes be identified by the tri type of tricone bits which have been used to drill them in the past. Where good bit runs have been turned in with the following tri-cone bit types, PDC bits should be examined as an improved alternative for future runs:

| Tri-Cone Bit | Equivalent PDC Bit Features |
| :--- | :--- |
| Steel Tooth | High Cutter Exposure |
| IADC Codes | Low Back Rake Angle |
|  | Steel Body |
| 114,116 | Long Taper or Step Profile |
| 124,125 | Low/Medium Cutter Density |
| TCI Tooth | High or Partial Exposure |
| IADC Code | High Back Rake Angle |
|  | Matrix Body |
| 517,527 | Flat or Short Profile |
|  | High Cutter Density |
| Reference: Chevron Drilling Reference Series Volume 9 |  |

Table 2.1: General Roller Cone versus PDC Bit Comparison.

An additional requirement for a successful PDC bit run is that the compatible formation be of sufficient thickness to keep the PDC bit in the hole for a long time. The section should be homogeneous with an absence of hard stringers. Sometimes however, it is possible to "nurse" a PDC bit through a hard section by feathering the formation with reduced rotary speed.

## Downhole Turbines or Dynadrills

PDC bits drill best with high RPM's and low bit weights. Therefore, mud motors are a natural compliment to their drilling ability. The absence of roller bearings on PDC bits allows them to handle the high RM's without coming apart.

## Slimhole Drilling

When the OD of a tri-cone bit gets below $6-1 / 2$ ", the strength of its bearings is greatly reduced. This requires reduced bit weight and causes slower drilling. PDC bits do not have bearings so they are not similarly restricted. For a PDC bit, the total weight on bit is restricted only by the weight per cutter which remains constant regardless of bit diameter.

## High Bottomhole Temperature

Roller cone bearing seals are prone to fail in high temperature environments. PDC bits may be a good substitute in hot holes if bearing seal failures are a problem. As always, the formation lithology should be checked for compatibility.

## Oil Base Mud

Roller cone bits will often drill more slowly in oil base mud than in fresh water mud. PDC bits however have had some exceptional bits runs through compatible formations when oil base mud has been in use. It is reasoned that oil mud penetrates the formation ahead of the bit and adds lubricity along the shear planes. The rock then fails more easily when a shear stress is applied by the bit.

## Drilling Overbalanced

When the mud overbalance is greater than 500 psi , the shearing action of a PDC bit will help to keep the penetration rate up. The cutting action of a PDC bit lifts the cuttings naturally and minimizes the "chip hold down effect" experienced with roller cone bits.

## Deviation Control

Dropping angle by reducing bit weight on a roller cone bit will often cause the penetration to drop dramatically. Running light weight on a PDC will sometimes allow the hole to drop angle without reducing the ROP. In non-directional wells, the combination of low bit weight and high RPM on a well stabilized string will usually keep the hole straight.

## Multi-Well Drilling Programs

A PDC bit can be run in successive wells to justify the cost when it would not pay out on a single well. If a used PDC bit is kept on location, extreme care should be taken to see that it is handled and stored properly.

### 2.7 PDC OPERATING PROCEDURES

On a drilling rig, where the most difficult problems are frequently solved by obtaining a bigger hammer, instructions to "take it easy" often go unheeded. It can therefore be difficult to obtain the kind of careful treatment for a PDC bit that it must have in order to make a good run.

Many of the following rules for running PDC bits are concerned with handling and running procedures. It seems odd that the instrument of destruction can itself be destroyed by something as simple as rough handling but many a PDC bit has been partially destroyed because these rules were not followed.

### 2.7.1 Rules For Running PDC Bits

- Note the rotary torque under normal drilling conditions before pulling out of the hole.
- Gauge the bit to determine if reaming will be required.
- Examine the bit for any broken inserts, lost nozzles, etc., which could mean junk in the hole.
- Do not run the PDC bit on junk. Run a junk bit or cleanup mill and junk basket if necessary. A good practice is to run a junk basket on the bit preceding the PDC bit run.

### 2.7.2 Handle the PDC carefully on the floor

- Use all handling precautions normally used on diamond bits to protect the brittle and expensive PDC cutters.
- Carefully remove the bit from its container and place it on a piece of plywood or a rubber mat.
-Do not roll the PDC bit on steel floor plates.

### 2.7.3 Examine the PDCbit making it up

- Gauge the bit to ensure it is the right size.
- Inspect the cutters for any damage.
- Record the serial number, nozzle number, sizes and date.
- Nozzle up the bit, if required, taking care not to damage the O-ring seals in the nozzle seats.

### 2.7.4 Make up the Bit carefully

- Use the appropriate bit breaker. Make up the bit to the API torque specifications for the standard pin size.

### 2.7.5 Use extreme caution while tripping in the Hole

- Be careful going through the rotary table, BOP's casing shoes and liner tops.
-Be wary of tight spots or ledges in the hole. PDC bits are not flexible like roller cone bits when going through tight spots. You must ream your way through tight spots to ensure that the bit is not stuck or damaged.
- If a tight spot is encountered, pick up the Kelly and pump at maximum flow rate. Turn the rotary about 60 RPM and advance slowly through the tight spot using no more than 40001 bs weight. Remember when reaming, all WOB is supported by gauge cutters making them heavily loaded even at light WOB.
- If the previous bit was under gauge, reaming to bottom will be necessary using the reaming procedure described above.
- Always wash the last joint slowly to bottom. PDC bit nozzles are very close to bottom and are easily plugged if the bit is jammed into fill. It is good practice to use nozzle protectors. Also, the bit could be easily balled-up if jammed into fill. Drillpipe screens at the surface can also prevent nozzle plugging.
- Locate bottom carefully using both rotary and WOB. Because PDC bits can generate high torque with their aggressive cutters and very little WOB, a sudden torque increase is often the first onbottom indication especially on small diameter bits.
- After bottom is found, lift the bit 6 " off bottom while circulating and rotating slowly for 10 minutes to make certain the bottom of the hole is clean.

### 2.7.6 Establish a new bottom hole pattern

- Use about 60 RPM and approach bottom carefully allowing no more than 100 lbs WOB per PDC cutter on the bit. For example, if the bit has 40 cutters then use no more than 4000 lbs WOB.
- Drill one foot in this manner to establish the new bottomhole pattern before beginning to optimize weight and WOB. The bit will be in the hole for a long time; do not rush. Apply weight slowly and gradually increase rotary speed until the observed rotary torque is slightly higher than it was with the last roller cone bit. This will be close to the optimum WOB and RPM combination. - Operating bit weights should be in the range from 600-2700 pounds per square inch of bit diameter. Higher rotating speeds (when mud turbines are used) will require bit weights in the lower range.

### 2.7.7 Optimize Weight on bit and rotary speed.

- Drill-off tests should be conducted in the good manner. Do not "bet the bank" early-on and stack out the entire collar on the first drill-off test. Add just a few increments of 1000-2000 pounds for each DOT and examine the results before adding more weight.
- PDC bit torque is very responsive to changes in bit weight. Notify your driller of this fact.
- If a hard streak is encountered, slow down the rotary table to reduce heat input into the cutters and avoid excessive cutter wear.

## - Never spud a PDC bit.

- Generally, hydraulic horsepower at the bit should be in the range from 2.5 to $4.5 \mathrm{HP} / \mathrm{in}^{2}$ for steel body bits and up to $7.5 \mathrm{HP} / \mathrm{in}^{2}$ for matrix body bits in sticky formations with water base mud.

### 2.8 DIAMOND BITS

Diamonds used in oilfield bits are of natural origin and range from as small as 15 tonnes per carat to as large as seven carats per stone. Diamonds are resistant to abrasion, extremely high in compressive strength (the hardest material known) but are low in tensile strength and have high thermal capacity. The low tensile strength reduces its ability to withstand impacts.

A diamond bit (either for drilling or coring) is composed of three parts: Diamonds, Matrix and Shank. The diamonds are held in place by the matrix which is bonded to the steel shank. The
matrix is principally powdered tungsten carbide infiltrated with a metal bonding material. The tungsten carbide is used for its abrasive wear and erosion resistant properties (but far from a diamond in this respect). The shank of steel affords structural strength and makes a suitable means to attach the bit to the drill string.

### 2.8.1 Uses of Diamond Bits.

The decision to run a diamond bit should be based on a detailed cost analysis in combination with many bit selection. The drilling situations which indicate the likelihood of an economical application for diamond bits includes the followings;

Very Short Roller Cone Bit Life: If Roller Cone bit life is very short due to bearing failure, tooth wear or tooth breakage, a diamond bit can increase on-bottom time dramatically. Diamond bit have no bearings and each diamond has a compressive strength of $1,261,000$ psi (approximately 1.5 times that of sintered tungsten carbide). ${ }^{3}$ The relative wear resistance is approximately 100 times that of tungsten carbide.

Lower Penetration Rates with Roller Cone Bits: When Roller Cone bits drill at slow rates (especially $5 \mathrm{ft} / \mathrm{hr}$ or less), due to high mud weights or limited rig hydraulics, diamond bit can provide a savings. Since the drilling fluid is usually distributed between the bit face and the formation in a smooth uniform sheet, it takes less hydraulic horsepower per inch to clean under a diamond bit than under the same size roller cone bit.

Deep, Small holes: Roller cone bits that are 6" and smaller have limited life due to the space limitation on the bearings, cone shell thickness, etc. Diamond bits being one solid piece often last much longer in very small boreholes.

Directional drilling: Diamond side tracking bits are designed to drill "sideways" making it a natural choice for "kicking off" in directional drilling situations.

Limited Bit Weight: Diamond bits drill at higher rates of penetration with less weight than normally required for roller cone bits in the same size range.

Downhole Motor Application: Roller Cone bits generally have bearing failures on motor applications due to high rotary speeds. Diamond bits will have a very long life under these conditions.

Cutting Casing Windows: Window cutting through casing using diamond bits is now an effective, field-proven method for re-entering older wells to increase production, to apply directional drilling techniques or to sidetrack.

Coring: The use of diamond bits for coring operations is essential for smooth, whole cores. Longer cores are possible with increased on-bottom time and cores "look better" because of the cutting action of diamond bits as compared to roller cone bits.

### 2.8.2 Limitations of Diamond Bits

Very Hard Broken Formation: Broken formations can cause severe shock loading on diamond bits resulting in diamond breakage and a short bit life.

Formation Containing Chert or Pyrite: Chert and Pyrite tend to break apart in large pieces and "roll" under a under a diamond bit, causing diamond damage.

Reaming Long Sections In Hard Formations: The hydraulic cooling and cleaning are extremely poor during reaming since the nozzles of a diamond bit are formed by the formation on side and bit matrix on the other side.

### 2.8.3 Bits Stabilization

A diamond is extremely strong in compression but relatively weak in shear and needs constant cooling when on bottom. The bit is designed and the rake of the diamonds set, so that a constant vertical load on the bit keeps an even compressive load on the diamonds and even distribution of coolant fluid over the bit face. If there is lateral movement or tilting of the bit, an uneven shear load can be put on the diamonds with coolant leakage on the opposite side of the bit.

## CHAPTER 3

 DRILLING OPTIMAZATION MODELSA good number of drilling optimization models have been published by different authors and they shall be expressly reviewed in this section of this project work.

### 3.1 SeROP MODEL

The Specific Energy Rate of Penetration (SeROP) model has been proved valuable for improving drilling performance. The SeROP model reduces well cost by improving bit performance prediction, bit selection and determination of optimum drilling parameters.
This technology makes it possible to select the optimum drill bits and stands to reduce the bit optimization learning curve from several wells to one. The method is global and robust, based on specific energy principles and confined compressive strength (CCS). It requires little or no calibration. Any calibration that may be required is intuitive and simple.

Specific energy theory is not new. Specific energy principles have been used for years to provide a method to predict or analyze bit performance. Specific energy is based on fundamental principles related to the amount of energy required to destroy a unit volume of rock and to the efficiency of bits to destroy the rock ${ }^{23}$. The specific energy parameter is the most useful measurement tool for predicting the power requirements (torque) for a particular bit might be expected to achieve in any rock type. The equation (1) shows the specific energy equation derived for rotary drilling at atmospheric conditions ${ }^{23,21}$.

$$
\begin{equation*}
\mathrm{S}_{\mathrm{e}}=\frac{\mathrm{WOB}}{\mathrm{~A}_{\mathrm{B}}}+\frac{120 * \pi * \mathrm{~N} * \mathrm{~T}}{\mathrm{~A}_{\mathrm{B}} * \mathrm{ROP}} . \tag{3.1}
\end{equation*}
$$

Where
$\mathrm{S}_{\mathrm{e}}=$ Specific energy (psi)
WOB $=$ Weight on bit (pound)
$\mathrm{A}_{\mathrm{B}}=$ Borehole area (sq-in)
$\mathrm{N}=$ Revolution per minute
$\mathrm{T}=$ Torque (ft-lbf)
ROP $=$ Rate of Penetration ( $\mathrm{ft} / \mathrm{hr}$ ) 3ithew

Because the majority of field data consists of surface measurements of weight on bit (WOB), rpm $(\mathrm{N})$ and rate of penetration (ROP), a bit-specific coefficient of sliding friction $(\mu)$ was introduced to express torque $(\mathrm{T})$ as a function of $\mathrm{WOB}^{23}$.

$$
\begin{equation*}
\mu=36 \frac{T_{\mathrm{B}}}{\mathrm{D}_{\mathrm{B}} * \mathrm{WOB}} . \tag{3.2}
\end{equation*}
$$

Where
$\mathrm{T}_{\mathrm{B}}=$ Bit torque (ft-lbf)
$\mathrm{D}_{\mathrm{B}}=$ Bit size (inches)
$\mu=$ Bit-specific coefficient of sliding friction (dimensionless)

Specific energy theory also defines the concept of minimum specific energy and maximum mechanical efficiency ${ }^{23}$. The minimum specific energy is reached when the specific energy approaches or is roughly equal to the rock strength being drilled. The mechanical efficiency $\left(E F F_{M}\right)$ for any bit type is then calculated as shown in equation (3):

$$
\begin{equation*}
\mathrm{EFF}_{\mathrm{M}}=\frac{\mathrm{E}_{\mathrm{Smin}}}{\mathrm{E}_{\mathrm{S}}} * 100 \tag{3.3}
\end{equation*}
$$

Where
$\mathrm{E}_{\mathrm{Smin}}=$ Rock strength (CCS in psi)
$\mathrm{EFF}_{\mathrm{M}}=$ Bit mechanical efficiency (\%)

The SeROP model uses confined compressive strength (CCS). This new proprietary methodology differs from existing ROP prediction methods that are based on unconfined compressive strength (UCS). UCS can be erroneous and or require calibration whenever the drilling environment changes. Because of this, UCS lacks the accuracy needed to predict ROP.

CCS calculates the altered pore pressure at the bottom of the hole directly below the bit. It also promotes a more accurate prediction of the confining stress (due to mud ECD and pore pressure
differential), leading to a more accurate prediction of confined rock strength or "apparent" strength to the bit.

Chevron developed this proprietary, unique and revolutionary method of predicting the coefficients required for equation (4) as a function of rock strength (CCS). This method was done for all predominant bit types including steel tooth, insert tooth, PDC, TSP, impregnated and natural diamond bit types. The relationships for bit-specific coefficient of sliding friction ( $\mu$ ) mechanical efficiency $\left(\mathrm{EFF}_{\mathrm{M}}\right)$ as a function of rock strength (CCS) were accurately determined from full-scale drilling simulator tests ${ }^{23}$.

Using this new capability and the globally-applicable rock property determination techniques, the ROP for all of the bit types with reasonable accuracy and no calibration can quickly be calculated. The approach can also be easily updated as technology advances because it is based on fundamental rock destruction principles and on conservation of methodology and work process is relatively simple in comparison to other ROP predictive processes used in the industry. A skilled drilling engineer could use the methodology. It does not require a specialist.

By substituting specific energy in terms of mechanical efficiency and CCS and torque as a function of WOB and solving equation (1) for ROP, the rate of penetration for any bit type can be calculated with equation (4) as follows:
$\mathrm{ROP}=\frac{13.33 * \mu * \mathrm{~N}}{\mathrm{D}_{\mathrm{B}}\left(\frac{\mathrm{CCS}}{\mathrm{EFF}_{\mathrm{M}} * \mathrm{WOB}}-\frac{1}{\mathrm{~A}_{\mathrm{B}}}\right)}$

The effect of mud weight, mud system, blade count, back rake angle, cutter size to the coefficient of sliding friction and mechanical efficiency are also considered in the ROP predictions.

Figure 3.1: Rock Mechanics (RMA), Confined Compressive Strength (CCS) and Specific energy Rate of Penetration (SeROP) flowchart.

### 3.2 RATE OF PENETRATION (ROP) MODELS

Hareland, et al ${ }^{4}$ introduced ROP model approach for bit performance. The general form of ROP equation for a 100 percent efficient bit cleaning is:
$\mathrm{ROP}=\mathrm{W}_{\mathrm{f}} *\left(\frac{G \cdot R P M_{l}^{\gamma} \cdot W O B^{\alpha}}{D_{B} S}\right)$
G is a coefficient determined by the bit geometry, cutter size and design (backrake and siderake angles) and cutter-rock coefficient of friction. $\mathrm{W}_{\mathrm{f}}$ is standing for wear function, estimating how much of new bit ROP is approachable by a bit with certain bit wear value. Equation (3.6) is developed to estimate Wear function based on single cutter experimental data ${ }^{4}$.
$\mathrm{W}_{\mathrm{f}}=\mathrm{k}_{\mathrm{wf}}\left(\frac{W O B}{N_{c}}\right)^{\rho} * \frac{1}{S^{\tau} A_{w}{ }^{\rho+1}}$
$\mathrm{A}_{\mathrm{w}}$ is wear flat area underneath of a single cutter which is a function of wear depth on cutter face and PDC layer thickness. It has to be mentioned that rock strength value in equation (3.5) and (3.6) is confined rock strength. The effect of confining pressure on rock strength can be estimated by:
$\mathrm{S}=\mathrm{S}_{0}\left(1-a_{s} \cdot P_{c}^{b_{s}}\right)$
$S_{o}$ and $P_{c}$ are rock unconfined strength and confinement pressure respectively. Confinement pressure is defined as pressure difference of mud hydraulic pressure and rock pore pressure which is a positive value in overbalanced situation.
" $a_{s}$ " and " $\mathrm{b}_{\mathrm{s}}$ " are coefficients depending on rock lithology.
Wear depth on cutter face or equivalent IADC bit wear is defined to be a function of removed cutter volume due to friction. Removed cutter volume is assumed to be proportional to cumulative effect of applied operational parameters (WOB, RPM) and rock confined strength and its relative abrasiveness in previously drilled footages by the bit as:
$V_{e q}=C_{a} \cdot \sum_{d=d_{i n}}^{d_{\text {out }}}\left(\frac{W O B_{d}}{1000 \cdot N_{c}}\right)^{C_{1}} \cdot R P M_{t d}{ }^{C_{2}} \cdot\left(\frac{s_{d}}{1000}\right) \cdot A b r_{d}$

The proportionality factor is a function of PDC layer material durability $\left(\mathrm{C}_{\mathrm{a}}\right)$ and relative hardness of cutter Tungsten carbide matrix to PDC layer material.

Based on approach followed for developing ROP model, required torque for drilling in perfect cleaning condition can be estimated by:
$T=C_{T 1} \cdot \frac{S \cdot R O P}{R P M_{l}}+C_{T 2} \cdot W O B \cdot D_{B}$
$\mathrm{C}_{\mathrm{T} 1}$ and $\mathrm{C}_{\mathrm{T} 2}$ are coefficients which are determined from bit design, cutter geometry and coefficient of friction between rock and cutters. It is clear that bit cutter wear affects drilling torque which is obtained from the ROP value.
Several ROP models have been proposed to combine known experimental or mathematic derived relationship between operating conditions and rate of penetration. These models make it possible

to apply formal optimization methods to the problem of selecting the best weight on bit rotary speed to achieve the minimum cost per foot. By utilizing ROP models significant drilling cost reductions and increase in rate of penetration has been reported ( Nygaard, et al. 2002, Hareland et al 2007).

### 3.2.1 Borgouyne \& Young ROP Model

In this model, penetration rate is a function of several variables such as sediments compaction, pore pressure, bit weight, rotary speed, impact force, bit hydraulics; cutter wear (Borguoyne and Young 1974). The model is mathematically expressed as:

$$
\begin{equation*}
\mathrm{ROP}=\mathrm{f}_{1} * \mathrm{f}_{2} * \mathrm{f}_{3} * \mathrm{f}_{4} * \mathrm{f}_{5} * \mathrm{f}_{6} * \mathrm{f}_{7} * \mathrm{f}_{8} \tag{3.10}
\end{equation*}
$$

Where $f_{1}$ to $f_{8}$ expresses the different effects on ROP such as rock drillability, operational parameter and bit wear. In the $f_{1}$ to $f_{8}$ functions formulas $a_{1}$ to $a_{2}$ are experimental model constants. $f_{1}$ is the effect of rock drillability which is proportional with formation rock strength and is given by;
$\mathrm{f}_{1}=e^{2.303 a_{1}}$
The second term is the depth effect given as:
$\mathrm{f}_{2}=e^{2.303 a_{a_{2}}(1000-\mathrm{D})}$
where D is depth in feet. The third term is the effect pore pressure has on ROP where overpressure will increase ROP and $f_{3}$ is given:
$\mathrm{f}_{3}=e^{2.303 a_{3} D^{0.69}\left(g_{p}-9\right)}$
where $g_{p}$ is the pore pressure in pounds per gallon equivalent. The fourth term is the effect of overbalance on ROP caused by mud weight increase.
$\mathrm{f}_{4}=e^{2.303 a_{3} D^{0.69}\left(g_{p}-P_{c}\right)}$
where $P_{c}$ is mud weight in pounds per gallon. The fifth term is the effect on ROP caused by changing the weight on bit.

Tinture
$\mathrm{f}_{5}=\left[\frac{\left(\frac{w}{d_{B}}\right)-\left(\frac{w}{d_{B}}\right)_{t}}{4-\left(\frac{w}{d}\right)_{t}}\right]^{a_{5}}$
where w is weight on bit, $\mathrm{d}_{\mathrm{B}}$ is the bit diameter. The sixth term is the effect of rotary speed on ROP.
$\mathrm{f}_{6}=\left(\frac{N}{60}\right)^{a_{6}}$.
where N is revolution per minute. The seventh term is the effect of bit wear on ROP.
$\mathrm{f}_{7}=e^{-a_{7} h}$.
where h gives the amount of bit wear for a bit. The last is the jet impact force effect which includes the effect of bit hydraulics on ROP. $\mathrm{F}_{\mathrm{j}}$ is further described in Borgouyne and Young (1974).
$\mathrm{f}_{8}=\left(\frac{F_{j}}{100}\right)^{a_{8}}$

### 3.2.2 Mechanical Specific Energy (MSE)

The concept of Mechanical Specific Energy is defined as the work required to destroy a given volume of the rock. The MSE monitoring process can provide the ability to detect changes in drilling efficiency which possibly can be used to optimize operating parameters. By definition it can be defined as input energy to the output ROP. The MSE equation can be expressed in terms of drilling parameters can as:
$\mathrm{MSE}=\frac{W O B}{A_{B}}+\frac{120 \pi N T}{A_{B} R O P}$.

In above formula $\mathrm{A}_{\mathrm{B}}$ is bit surface area (inch ${ }^{2}$ ), N is rotary speed (Round per minute), T is measured Torque ( $l b f^{*} f t$ ) and MSE in $p s i$ (B Rashidi). ${ }^{21}$

In equation 3.19, torque is used as a variable in the MSE calculation formula. Torque at the bit can be measured by a MWD system but in most cases no bit's torque measurement exist. Bit specific coefficient of sliding friction $(\mu)$ is introduced to express torque as a function of the WOB and to let the MSE to be calculated in the absence of reliable torque measurement.
$\mathrm{T}=\mu \frac{D_{B} W O B}{36}$
Combining equations 3.1 and 3.2, a new form of MSE is derived and is called the modified MSE shown as :
$\operatorname{MSE}_{\text {mod }}=\operatorname{WOB}\left(\frac{1}{A_{B}}+\frac{13.33 \mu N}{D_{B} R O P}\right)$.

The "sliding" coefficient" friction coefficient is a constant dimensionless number which is used with a specific value for Roller Cone and PDC bits. The exact bit "sliding" friction coefficient value can be obtained using the measured torque and WOB in the laboratory ${ }^{21}$.

### 3.2.3 Real-Time Bit Wear Model Development

In the Burgouyne and Young ROP model, the ROP is defined as the effect of eight functions which can be inverted to obtain the drillability noted as the $\mathrm{f}_{1}$ function $(\mathrm{ft} / \mathrm{hr})$.

Offset well drilling data such as ROP, WOB, RPM, flow rate, mud weight and pore pressure from each meter or foot of drilled well can be used to estimate the rock drillability value as below:

$$
\begin{equation*}
f_{1}=\frac{R O P}{f_{2} f_{3} * f_{4} * f_{5} * f_{6} * f_{7} * f_{8}} . \tag{3.20}
\end{equation*}
$$

Fractional bit wear is simplified and assumed as linear decreasing using the below equation:

$$
\begin{equation*}
h=\frac{\left(\text { Depth }_{\text {current }}-\text { Depth }_{\text {in }}\right)}{\left(\text { Depth }_{\text {out }}-\text { Depth }_{\text {in }}\right)} * \frac{D G}{8} . \tag{3.21}
\end{equation*}
$$

DG in above equation is the IADC dull grade bit wear state which is reported when the bit is pulled and has a value between 0 and 8 and is shown in Figure 2.8 for both Roller Cone and PDC bits.

Mechanical specific energy uses the ROP value directly in its formula. To find a relationship between MSE value and rock drillability a new model was suggested ${ }^{21}$.

The new model is originally proposed in the power form as:

Tinture
$M S E=K_{l}\left(\frac{1}{f_{1}}\right)^{K_{2}}$.
where $\mathrm{K}_{1}$ and $\mathrm{K}_{2}$ are constants verifiable with offset drilling data. The constants vary from field to field.

### 3.2.4 Rock Strength Calculations

The rock mechanical parameters most important when conducting drilling analysis is unconfined compressive rock strength (UCS). ${ }^{16}$ the UCS can be determined from Mohr Coulomb failure criteria. The Mohr-Coulomb failure criterion in terms of peak loads is given as:
$S^{\prime}{ }_{v}=U C S+S^{\prime}{ }_{h} \tan \alpha$
where $S_{v}^{\prime}$ is vertical effective stress, $S^{\prime}{ }_{h}$ is horizontal effective stress and $\alpha$ is failure angle. Effective stresses are defined as the difference between total stresses and pore pressure.
$S_{v}^{\prime}=S_{v}-p p$
$S_{v}$ is the total stress and $p p$ is the pore pressure.

The Apparent Rock Strength based on the inverted ROP model for a specific bit has been presented for a roller cone bit as follows ${ }^{10}$.
$R O P=\left[f(h y d)\left[\frac{a S^{(2-b s)} d_{b}{ }^{2}}{R P M \cdot W O B^{(2-b s)}}\right]\right]^{-1} \ldots$
$R O P$ is Rate of Penetration, $W_{f}$ is wear factor that takes into account wear of the bit, $f(h y d)$ is a function that takes into account any of the hydraulic effects such as flow and mud properties, $S$ is the rock strength named ARSL, $R P M$ is revolution per minute, $W O B$ is weight on Bit, $d_{b}$ is bit diameter and $a, b s$ are laboratory derived model constants. After a well is drilled all information is known except the Rock strength $S$. The rock strength can be calculated by inverting the Roller Cone bit ROP model in equation 3.25 .

There are several methods to obtain Unconfined Compressive Strength (UCS) of rock along the well bore. In most cases, the availability of data determines which methods to choose. Different methods of obtaining UCS are described below:

Rock mechanical laboratory testing on preserved core samples are the most accurate method for calculating rock strength.

The use of logs (sonic velocity logs, neutron logs, Porosity or combination) to determine elastic properties of rock is well established. Several correlations between rock strength and sonic travel have been published. ${ }^{16}$

To overcome the time-consuming tri-axial, rock mechanical strength from cuttings is conducted on small cutting samples.

The use of drilling data to predict rock strength has been developed based on Rate of penetration (ROP) models. ${ }^{4-23}$

### 3.3 THE COST PER FOOT EQUATIONS

Drilling optimization is the application of technology which yields a reduction of drilling costs associated with making hole. The following optimization techniques are popular in drilling:
-Cost per foot equation
-Time value of money
-Expected value method
-Lagrangian multiplier
-Multiple regression
-Confidence intervals
-Lagrange's interpolation formula.
Only the cost per equation will be given light here. The cost per foot equation is used for the comparison of alternative equipment, chemicals and procedures for the drilling of a formation or an interval. The comparisons are often called break-even calculatios and are usually between drill bit types or manufacturers; however, any of the variables may be compared.

$$
C=\frac{\text { Bit }+ \text { Tools }+ \text { Mud }+[\text { DrillTime }+ \text { Trip }+ \text { Lost }][\text { Rig }+ \text { Support }+ \text { ToolRental }]}{\text { Drill Rate } * \text { Drill Time }}
$$

Where
C = cost per foot for interval of concern, $\$ / \mathrm{ft}$
Bit $=$ Cost of delivered bit at the drill site, $\$$
Tools $=$ Cost of tools or Repairs totools, $\$$
Mud = Cost of mud to drill the interval, \$
Drill Time $=$ Time required to drill the interval or bit life, hr
Trip $=$ Time to pull and run a bit, hr
Lost $=$ Time chargeable to non-drilling task, hr
Rig = Contract rental rate of a rig, $\$ / \mathrm{hr}$
Support = Third party contractors rates, $\$ / \mathrm{hr}$
Tool Rental = Rental of tools, \$/hr
Drill Rate $=$ Average drilling rate over the interval, ft/hr

In a comparison of drill bits, the drilling rate and life of the proposed bit will always be in question. The usual procedure is to compute the cost per foot with the data from a standard bit with the proposed bit; and then construct a chart of required drilling rate and bit life for the proposed bit. ${ }^{22}$

## CHAPTER 4 BIT PERFORMANCE OPTIMIZATION SIMULATION

The first phase of the optimization process involves the selection of a reference well which closely matches the planned well. Using the data from the reference well, a Geologic Drilling Log (Apparent Rock Strength Log- ARSL) ${ }^{4,1,2}$ is generated by the inversion of the bit specific rate of penetration models. The effects of operating parameter, bit design and wear, drilling hydraulics, mud rheology and pore pressure being integral to the model.

The inverted rate of penetration provided a calibrated measure of the rock strength under actual drilling conditions and simultaneously determines the wear characteristic of the bits used in drilling the relevant sections.

The wear characteristic is a statistical evaluation of the bits performance while drilling varying formation types and under a variety of operating conditions and includes detailed bit geometry and its resistance to wear.

### 4.1 APPARENT ROCK STRENGTH LOG (ARSL) APPLICATIONS

ARSL is applied in the determination of wellbore stability profile. This is important to minimize the occurrences of wellbore collapse, pipe sticking, loss circulation and the host of others. The ARSL represents the compressive strength of the rock in the same plane as the bit's trajectory.

The application of ARSL is also in the determination of the ability of 3D rotary assemblies to steer effectively. The relationship between the behavior of a rotary steerable bottom hole assembly and changes in apparent rock strengths has been determined by correlating tool behavior with data obtained from ARSL.

ARSL is used in combination with established casing points, well paths, drilling mode (rotary or steerable system), mud types, bit types, pull depths, operating conditions and mud rheology/hydraulics to perform simulations. The ARSL with information from simulator modules, known limitations to operating parameters and rig equipment constraint dictates parameter to be used ${ }^{14}$.

### 4.2 DROPS SIMULATOR OPTIMIZATION

In the actual optimization of bit performance simulation, two reference wells A and B were used. They are Conoco Phillips wells selected from Ekofisk/Eldfisk field of the North Sea.

Halliburton (Sperry Drilling Services) was the Drilling vendor who provided the drilling operating parameters, some of the bit information, survey data and drilling fluid properties needed while the lithology information, the rest of the bit information and pore pressure profile were obtained directly via a contact from Conoco Phillips.

In order for the Drill Bit performance optimization to be simulated using the DROPS Simulator, the obtained data were categorized into the drilling operating parameters, survey data, lithology information and the bits information.

For the purpose of emphasis, only the obtained data for reference well A will be presented in the project work. Well B will be implied with the DROPS Simulator because of large depth volume it entails.

### 4.2.1 Drilling Operating Parameters for Well A

Table 4.1 Drilling Parameters for Well A
Mudtype(1=Oil, $0=$ Water) and Drilling Mode (R=Rotary,A=AutoBHA)

| Depth | TVD | ROP | WOB | RPMtotal | flow in | PV | MW | MUDTYPE | DMODE |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |

## CHAPTER 5 DISCUSSIONS AND CONCLUSIONS

Two selected reference Wells: A and B were analysed using the DROPS Simulator provided by Impetro International. Well A and Well B are both horizontal wells. These wells are considered to be problematic as they were associated with one problem of lost BHA, MWD failure or the other during the on-going drilling operation.

### 5.1 DISCUSSIONS

The input operating drilling parameters included the Measured Depth (MD) of the range of 5078 ft to 5435 ft for Well A and 5078 ft to 17837 ft for Well B with its corresponding True Vertical Depth (TVD), feet to feet Rate of Penetration (ROP), Weight on Bit (WOB), Revolution per minute (RPM), Pump rate(GPM), Plastic Viscosity (PV), Mud weight (MW), mud type and drilling mode all in field units.

The aforementioned drilling parameters were used alongside with its survey data (angle of inclination and azimuth angle) on feet to feet basis.

The lithology for both wells is assumed to be Shale the entire section and the reservoir rock is limestone. Since Shale is porous but not permeable, it takes the value of zero for permeability. Pore pressure from Ekofisk/Eldfisk field have been modeled and used widely from Figures 4.1 and 4.2. The pore pressure used in the lithology data was evaluated from these charts.

The bit information provided all bits run in the individual together with their dull bit grading, manufacturer, bit type, design, amongst other bit properties (backrake angles, siderake angles, number of cutters, number of blades, etc). An idea of bit dull grading in other wells drilled in the same field is presented in tables 4.5.3, 4.5.4 and 4.5.5 for comparison.
The bit performance optimization simulator puts together all the inpt data (drilling parameter, survey data, lithology and the bit information) and generated Apparent Rock Strength Log, average ROP, WOB, RPM, PV, MW, Bit Wear and predicts each section rate of penetration depending on the number of sectionsdrilled with different bits.

Using the simulator, the following assumption was made: 185000 \$/day used as Rig cost/day, $10000 \$ /$ day used for Mud \& MWD cost/day, 5 minutes/30feet used as connection time and 1 hour/1000feet real time used as trip time. Note: PDC1 and PDC2 in Well A are different from the

PDC1 and PDC2 in Well B in terms of design, manufacturer, configurations and drilling potentials.

Well A: The first section drilled with PDC1 has the length of 42 ft which gave an average ROP of $19.97 \mathrm{ft} / \mathrm{hr}$ with cost/ft of $2358.03 \$ / \mathrm{ft}$ while the second section drilled with PDC2 has the length of 314 ft having an average ROP of $68.77 \mathrm{ft} / \mathrm{hr}$ with cost/ ft of $453.63 \$ / \mathrm{ft}$ given by the simulator.
The simulator combines the average results above to give an overall result summary before simulation of $709.4 \$ / \mathrm{ft}$ of the two sections within the drilling time of 6.6 hours. After simulation, the cost/ft falls to $688.7 \$ / \mathrm{ft}$ within the same drilling time of 6.7 hours. This has saved $20.7 \$ / \mathrm{ft}$ and cumulatively saved $\$ 7,389.9$ through the entire length of Well A.

If actual real-time data are used in the optimization and simulation process muchmore appreciable amount could be saved.

Different bits PDC1,PDC2 and Bit 123456 were used in simulating the whole sections to see the best bit performance. The simulator predicted for Bit 123456: 26.8ft/hr ROP,cost/ft of $396.8 \$ / \mathrm{ft}$ within the drilling time of 4 hours, for PDC1: $0.2 \mathrm{ft} / \mathrm{hr}$ ROP,cost/ft of $16270.3 \$ / \mathrm{ft}$ withn the drilling time of 724.4 hours and for PDC2: $60.1 \mathrm{ft} / \mathrm{hr}$ ROP, cost/ft of $337.4 \$ / \mathrm{ft}$ within the drilling time of 1.8 hours. Based on wear constant, ROP, drilling time, and at large cost/ft PDC2 has given a better bit choice of selection among the available bits.

The lithology at the measured depth between 5078 ft and 5120 ft have Apparent Rock Strength (ARS) of the range of 0.4 Kpsi to 1.2 Kpsi corresponding with a higher ROP suggests a relatively harder formation. While the rest of the entire well have ARS of alower range 0.1 Kpsi to 0.3 Kpsi with higher ROP implies a relative softer formation.

Well B: Well B has the same first drilled section with Well A. 19.97ft/hr ROP and having average cost/ft of $2358.03 \$ / \mathrm{ft}$. The second drilled section, 1015.1 ft , with PDC2 has average ROP of $208.1 \mathrm{ft} / \mathrm{hr}$ having an average cost/ft of $73.49 \$ / \mathrm{ft}$. The simulator on combining the two sections before running the simulation predicted cost/ft of $87.6 \$ / \mathrm{ft}$ within the drilling time of 64.1 hours while after simulation the cost/ft drops to $81.4 \$ / \mathrm{ft}$ within the drilling time of 63.2 hours. This is saving $6.2 \$ / f t$ and a cumulative savings of $\$ 26,4332.04$ through the entire length of Well B.

The whole section of Well B when simulated with PDC1 and PDC2 independently, PDC2 gave a much lower cost/ft of $81.4 \$ / \mathrm{ft}$ within the drilling time of 61.5 hours while PDC 1 gave cost/ft of
$82.1 \$ / \mathrm{ft}$ within the drilling time of 63.2 hours. Obviously PDC2 produced a better drilling potentials than PDC1. This could also be justified by the predicted wear constants evaluated by the DROPS simulator as tabulated in table 4.6.5. The lower the wear constant of a Bit, the higher the resistant tendencies to wear while in a drilling operation.

At the measured depth of 7106 ft , the highest ARS value of 6.1 Kpsi is obtained while at 7150 ft , 0.15 Kpsi is obtained from the ARS log. Between 9220 ft and 9940 ft the range of ARS of 0.15 Kpsi to 3.08 Kpsi could be evaluated. A harder formation is suggested at the measured depth of 17070 ft to 17837 ft justified by the lower ROP. A better overview of the ARS can be gotten from the figures of plots generated in chapter 4 of this piece of research work.

The bit hydraulic analysis is another cardinal aspect to be considered when looking at Bit performance optimization, simulation and selection criteria. It is important as cuttings generated by bit needs to be removed as soon as they are produced to prevent bit-balling. Bit hydraulics is very necessary to all kinds of bit but more formidable to PDC bits as they have higher tendency of producing larger volume of cuttings than the rest type of bits.

From the bit hydraulic analysis conducted for Well A and Well B, a general trend is seen as the flowrate is varied from bit to bit. The larger the nozzle sizes and number, the lower the pressure drop across the bit and as well the lower the pressure effect. Conversely, the smaller the nozzle sizes and number, the higher the pressure drop across the bit and the higher the pressure effect as simulated by the DROPS simulator.

### 5.1.1 Limitations and Recommendations of this Research Work

This research work is limited by actual input data in the case of the complete bit information for Well A and Well B as the first section bit information was not available but assumed and that for the second section was lost in the hole hence the actual bit dull grading was assumed.
Again the percentage lithology composition was absolutely missing but ought to be explicitly input.
The models used by the DROPS simulator and how the plots for the various parameter is generated is beyond the scope of this project.

The Rig cost/day, Mud \& MWD cost, Number of connection / 1000feet and connection time/ 30ft were all assumed to give a better understanding.

### 5.2 CONCLUSIONS

The conclusions presented here is strictly based on the assumptions made, data obtained within our reach, the DROPS simulator evaluations and any other conditions considered in this project and therefore could give an idea of the most probable bit performance optimization choices or alternatives.

- The bit performance optimization and simulation reveals the overall simulation result summary before running simulation the cost/ft of $709.4 \$ / \mathrm{ft}$ within the drilling time of 6.6 hours and after running the simulation, the cost/ft falls to $688.7 \$ / \mathrm{ft}$ for the two sections within the drilling time of 6.7 hours. This have save $20.7 \$ / \mathrm{ft}$ and cumulatively saved $\$ 7,389.9$ through the entire length of Well A. Also, Well B has saving of $6.2 \$ / \mathrm{ft}$ and cumulative savings of $\$ 26,433.04$ through the entire drilled length of Well B having cost/ft of $87.6 \$ / \mathrm{ft}$ within the drilling time of 64.1 hours before simulation and the cost/ft of $81.4 \$ / \mathrm{ft}$ within the drilling time of 63.2 hours after simulation. Appreciable savings can be made if adequate data information is given.
- Using ROP, drilling time, bit wear constant, bit cost and at large cost/ft criteria PDC2 bit in both Wells have a better drilling potentials than PDC1.
-It can also be concluded that the first section of both Wells simulated have relatively harder formation than the second section. Stringers of harder formation could be found along the entire section of both Wells.
-The larger the nozzle sizes and number, the lower the pressure drop across the bit and the lower the pressure effect simulated as the flowrate varied incrementally.
-The ROP obtained by the simulator compares well with those obtained from actual data (see Appendix), UCS prediction, Bit pressure effect automatic evaluation among others shows that the DROPS simulator is robust and versatile.
